### (d) $\beta$ - Decay Stability

# Prediction of stability against $\beta$ -decay for members of an isobaric family (For Odd A and Even A isobars)

The  $\beta$ -decay process furnishes an isobaric pair which can be easily studied with the help of semi-empirical mass formula. There are two types of  $\beta$ -decay viz.  $\beta^+$  and  $\beta^-$ . In the  $\beta^-$ -decay, Z increases by 1-unit and in  $\beta^+$ -decay Z decreases by 1-unit, while A remains constant.

Energy Released in 
$$\beta^-$$
 -decay  $Q_{\beta^-} = M\left(Z,A\right) - M\left(Z+1,A\right);$   $\left(Z \to Z+1\right)$  Energy released in  $\beta^+$  - decay  $Q_{\beta^+} = M\left(Z,A\right) - M\left(Z-1,A\right);$   $\left(Z \to Z-1\right)$ 

### (a) Odd A Nuclei Decay

Since only one parabola, there is only one minimum value  $Z_0$ . Therefore we expect that for odd-A nuclei there is only one  $\beta$ - stable nucleus.

Only  $\beta^-$ - decay along the left arm and only  $\beta^+$ - decay for the right arm of the parabola because nuclei are driven towards achieving more stable states.

Energy released in  $\beta$ -decay varies with Z. Hence different transitions in the same parabola may release different amount of energy.

Now, energy released in decay is given by  $\beta^-$  - decay,

$$\begin{split} Q_{\beta^{-}} &= M\left(Z,A\right) - M\left(Z+1,A\right) = \left[M\left(Z,A\right) - M\left(Z_{0},A\right)\right] - \left[M\left(Z+1,A\right) - M\left(Z_{0},A\right)\right] \\ Q_{\beta^{-}} &= \gamma \left(Z-Z_{0}\right)^{2} - \gamma \left(Z+1-Z_{0}\right)^{2} = \gamma \left[-2\left(Z-Z_{0}\right) - 1\right] = 2\gamma \left(Z_{0}-Z-\frac{1}{2}\right) \\ \text{Thus, } Q_{\beta^{-}} &= 2\gamma \left(Z_{0}-Z-\frac{1}{2}\right) \text{ and similarly, } Q_{\beta^{+}} = 2\gamma \left(Z-Z_{0}-\frac{1}{2}\right) \end{split}$$

#### (b) Even A Nuclei Decay

Here the pairing term  $\delta \neq 0$  and since both odd-odd and even-even nuclei are included, we have two parabola, displaced in binding energy by  $2\delta$  or corresponding mass value.

The decay always terminates on the lower parabola because it represents greater stability. (An even-even nucleus makes the lower parabola). In each  $\beta$ - transformation an even-even nuclei changes to odd-odd nuclei and odd-odd nuclei changes to even-even. Hence in each  $\beta$ - transformation there will be jump from one parabola to the other parabola.
